

COUNTERBALANCED FLOW TURBINE NOZZLE

BACKGROUND OF THE INVENTION

[0001] The present invention relates generally to gas turbine engines, and, more specifically, to turbine nozzles therein.

[0002] In a gas turbine engine air is pressurized in a compressor and mixed with fuel in a combustor for generating hot combustion gases. Energy is extracted from the combustion gases in turbines, with a high pressure turbine (HPT) powering the compressor through a corresponding drive shaft therebetween, and a low pressure turbine providing output power such as powering a fan disposed upstream from the compressor in a turbofan aircraft engine application.

[0003] The typical compressor includes multiple axial stages having rotor blades decreasing in size in the downstream direction for pressurizing air in turn. The pressurized air supports combustion of the fuel injected into the combustor, and efficiency of the engine increases with the temperature of the hot combustion gases.

[0004] To withstand the hot combustion gases during operation the various combustor and turbine components subject to the heat thereof are typically made of advanced superalloy materials which maintain strength at elevated temperature and promote the durability and long life of the turbine engine. Furthermore, the various hot engine components are typically cooled using a portion of the pressurized air bled from the compressor and channeled through corresponding cooling circuits in the components.

[0005] However, any air bled from the compressor which is not utilized in the combustion process decreases the overall efficiency of the engine, and therefore must be kept to a minimum. Accordingly, durability and life of the engine must be balanced against the overall efficiency thereof.

[0006] The balance of life and efficiency typically requires various tradeoffs in the design of the various components of the engine, which components are inherently interrelated in function and performance. For example, the prior art relevant to cooling of gas turbine engine components is replete with numerous cooling circuit configurations which vary either greatly,

1 or with minor, but significant changes.

2 [0007] A common example is found in the various configurations of the first stage turbine
3 nozzle which directly receives the hottest combustion gases from the combustor. The high
4 pressure turbine nozzle is typically formed in arcuate segments having a pair of hollow nozzle
5 vanes fixedly joined to outer and inner bands. Pressurized cooling air is bled from the
6 discharge end of the compressor and suitably channeled to the turbine nozzle through the outer
7 or inner bands, or both.

8 [0008] Each nozzle vane has the typical airfoil configuration including a generally concave
9 pressure side and an opposite generally convex suction side which extend in chord axially
10 between leading and trailing edges. The profile of each vane is selected for maximizing
11 efficiency of the nozzle in redirecting the hot combustion gases to the downstream row of
12 HPT rotor blades which extract energy therefrom.

13 [0009] Each nozzle vane typically includes multiple flow passages or cavities therein
14 through which the cooling air is channeled in various, and commonly elaborate, cooling
15 circuits. The internal surfaces of the vanes typically include small turbulators or pins which
16 increase the heat transfer between the internal cooling air and the hot metal sidewalls.

17 [0010] Perforate impingement baffles are typically used in the first stage nozzle for initially
18 directing the cooling air in impingement against the internal surfaces of the vane prior to flow
19 thereof laterally along the inner surfaces for discharge from various outlets formed through the
20 vane sidewalls.

21 [0011] Since the vanes are directly exposed to the hottest combustion gases over their
22 external surfaces, they include various patterns of small outlet holes therethrough which cool
23 the sidewalls themselves, as well as providing a protective film of cooling air between the
24 vane and the hot combustion gases. Film cooling of the external surfaces of the vane is
25 typically provided by inclined film cooling holes extending through the pressure and suction
26 sides of the vane for ensuring a suitable cooling air film over the external surface of the vane.

27 [0012] Since the leading edge of each vane is firstly exposed to the hot combustion gases
28 which split along the opposite pressure and suction sides of the vane, the leading edge
29 typically requires specialized cooling thereof for meeting the desired life or durability
30 requirements of the nozzle.

1 [0013] The combustion gases flow differently over the concave pressure side than over the
2 convex suction side in view of the required aerodynamic performance of those sides for
3 proper efficiency of the turbine nozzle. Accordingly, the pressure and suction sides of each
4 vane have different configurations of the outlet holes therein intended to correspond with the
5 different pressure and temperature distributions of the combustion gases flowing thereover
6 during operation.

7 [0014] The vane airfoil converges in the axially downstream direction to a thin trailing edge
8 which limits the ability to introduce corresponding cooling circuits between the opposite
9 pressure and suction sides. A row of trailing edge outlets is provided in the trailing edge
10 where space permits for discharging some of the internal cooling air for locally cooling the
11 trailing edge region of the vane. In turbine nozzles, the trailing edge outlets are typically
12 located on the pressure side of the vane and terminate closely adjacent to the trailing edge.

13 [0015] Since gas turbine engines are designed in different configurations for different
14 applications including military, commercial, and industrial applications for powering aircraft,
15 ships, and electrical generators, the associated cooling configurations for the components
16 thereof also vary significantly. In commercial aircraft engines, for example, long life or
17 durability of the engine is desired for minimizing the periodic maintenance requirements
18 therefor, while high efficiency is also desired for decreasing the cost of operation. Long life
19 requires effective cooling, whereas high efficiency requires minimum bleeding of the cooling
20 airflow.

21 [0016] The numerous advances in design of the modern aircraft turbofan engine results in
22 both great efficiency and long life or durability, with actual operating experience now
23 uncovering localized distress in hot turbine components which affects the extended life
24 thereof. For example, the high pressure, first stage turbine nozzle that is subject to the hottest
25 combustion gases in gas turbine engines will eventually experience oxidation and localized
26 cracking of the vanes at the end of its life due to the repeated exposure to the hot combustion
27 gases. The local distress regions of the nozzle vane may be at any location depending upon
28 the specific design of the nozzle and engine, including the leading edge which first receives
29 the hot combustion gases, or the thin trailing edge, or in between.

30 [0017] As indicated above, the nozzle vane cooling configurations may be specifically

1 tailored for addressing the various cooling requirements thereof including the leading edge
2 and trailing edge regions, but this tailoring comes with a price. A given or limited amount of
3 cooling air is available for each nozzle vane, and that cooling air budget must be distributed
4 over the entire vane for selectively cooling the various portions thereof. Increasing cooling air
5 to one portion of the vane necessarily decreases cooling air to other portions for a given
6 cooling air budget.

7 **[0018]** Furthermore, redistributing the cooling air budget in a nozzle vane correspondingly
8 affects the overall cooling thereof, and may also affect the aerodynamic performance of the
9 nozzle itself as the cooling air is discharged through the various outlet holes covering the vane.
10 Yet further, the pressurized cooling air delivered to the turbine nozzle is a portion of the
11 highest pressure compressor discharge air, which discharge air is also used for cooling the
12 liners of the combustor itself. Another balance in the design is required for cooling the turbine
13 nozzle as well as the combustor liners using the same source air, with corresponding limited or
14 budgeted amounts thereof.

15 **[0019]** The great sophistication and complexity of designing modern turbofan engines is
16 further exemplified in evaluating a pre-existing first stage HPT nozzle which has been on sale
17 and in commercial public use for decades in the U.S. This extremely mature turbine nozzle
18 has continually undergone small changes in the configuration thereof for further enhancing its
19 performance and durability.

20 **[0020]** In particular, this pre-existing nozzle includes a pattern of outlet holes over both the
21 pressure and suction sides of the nozzle vanes which use the limited budget of cooling air for
22 effective cooling of the nozzle vanes for extended life and durability. The pattern includes
23 rows of showerhead film cooling holes bridging the pressure and suction sides of the vane at
24 the leading edge, and a row of trailing edge outlet slots along the pressure side. Rows of gill
25 film cooling holes are found in the suction side downstream of the showerhead holes, and
26 additional rows of film cooling holes are found on the pressure side downstream from the
27 showerhead holes.

28 **[0021]** The original configuration of this pre-existing design included eight rows of
29 showerhead holes bridging the leading edge. One row extended along the leading edge. Four
30 rows were disposed on the pressure side aft therefrom. And, three rows were disposed on the

1 suction side aft of the leading edge. These eight rows effectively cooled the leading edge
2 region of the nozzle vane.

3 **[0022]** However, actual operating experience uncovered local distress or oxidation on the
4 suction side downstream of the showerhead holes, and therefore in a modification of the
5 original design, the aft-most end row of showerhead holes on the pressure side was moved
6 from the pressure side to the suction side immediately downstream of the aft-most row of
7 showerhead holes on the suction side for maintaining the original cooling air budget while
8 addressing the local suction side distress. This modified nozzle vane has also enjoyed many
9 years of commercial public use and success in the U.S.

10 **[0023]** However, further experience in the use of this modified nozzle design is showing
11 local distress in the region of the pressure side leading edge where the first row of showerhead
12 holes was removed. Furthermore, additional local distress is also being experienced on the
13 suction side of the same vanes near the trailing edge.

14 **[0024]** This modified nozzle vane, like its parent, includes two rows of cylindrical film
15 cooling gill holes located immediately downstream of the showerhead holes on the suction
16 side of the vane that provide film cooling thereover to the trailing edge of the vane. Two rows
17 of such gill holes are used for minimizing the amount of cooling air required for cooling the
18 suction side of the vane.

19 **[0025]** In a second pre-existing first stage HPT nozzle design for a different turbofan gas
20 turbine engine enjoying many years of successful commercial public use in the U.S., a
21 different pattern of outlet holes is found over the pressure and suction sides of the nozzle vane,
22 including a pair of closely spaced film cooling gill holes disposed aft of multiple rows of
23 showerhead holes at the leading edge. This second pre-existing turbine nozzle also
24 experienced local distress over the suction side at the trailing edge, which was addressed by
25 spreading the aft row of gill holes downstream from the forward row of gill holes, and
26 changing the configurations thereof from conventional cylindrical film cooling holes to
27 conventional diffusion holes having cylindrical inlets and diverging outlets. The flow size of
28 these gill holes remained the same for maintaining the limited cooling air budget.

29 **[0026]** There are, of course, a multitude of solutions which may be used for attempting to
30 solve these problems of local distress at two different locations on the first pre-existing nozzle

1 vane on the pressure side leading edge and the suction side trailing edge. However, the desire
2 to maintain the same limited cooling air budget for turbine nozzle cooling substantially
3 increases the difficulty of the solution.

4 [0027] For example, merely re-introducing the removed row of pressure side showerhead
5 holes will correspondingly increase the cooling air requirement, which in turn can change the
6 overall cooling performance of the nozzle vane itself, the aerodynamic performance of the
7 nozzle, and the cooling performance of the combustion liners which also utilize compressor
8 discharge air for cooling. Attempting to decrease the size of the showerhead holes to limit the
9 need for additional cooling air, will correspondingly adversely affect their cooling
10 performance at the leading edge in particular.

11 [0028] Furthermore, resolving the local distress on the suction side trailing edge region can
12 also affect cooling performance of the entire nozzle, including the local distress at the pressure
13 side leading edge.

14 [0029] Accordingly, it is desired to provide a turbine nozzle having an improved
15 configuration for cooling thereof while maintaining a limited air budget therefor.

16

17 BRIEF DESCRIPTION OF THE INVENTION

18

19 [0030] A turbine nozzle includes hollow vanes extending between outer and inner bands.
20 The vanes include a pattern of outlet holes distributed over the pressure and suction sides
21 thereof for discharging cooling air collectively at a reference flowrate. The pattern of holes
22 includes multiple rows of showerhead holes bridging the leading edge, and two rows of gill
23 holes spaced aft therefrom along the suction side. A row of auxiliary holes is spaced aft from
24 the showerhead holes through the pressure side, and the gill holes are sized to counterbalance
25 the added discharge air through the auxiliary holes for maintaining the reference flowrate.

26

27 BRIEF DESCRIPTION OF THE DRAWINGS

28

29 [0031] The invention, in accordance with preferred and exemplary embodiments, together
30 with further objects and advantages thereof, is more particularly described in the following

1 detailed description taken in conjunction with the accompanying drawings in which:

2 **[0032]** Figure 1 is an isometric view of an arcuate portion of an annular first stage high
3 pressure turbine nozzle for a gas turbine engine.

4 **[0033]** Figure 2 is an exploded view of a segment of the nozzle illustrated in Figure 1.

5 **[0034]** Figure 3 is a radial sectional view through a pair of nozzle vanes illustrated in Figure
6 1 and taken along line 3-3.

7 **[0035]** Figure 4 is an enlarged isometric view of the leading edge portion of the nozzle vanes
8 from the pressure side.

9 **[0036]** Figure 5 is an enlarged isometric view of the leading edge portion of the nozzle vanes
10 from the suction side.

11

12 **DETAILED DESCRIPTION OF THE INVENTION**

13

14 **[0037]** Illustrated in Figure 1 is a portion of an annular first stage high pressure turbine
15 nozzle 10 which is axisymmetrical about a longitudinal or axial centerline axis. The nozzle is
16 configured for use in a gas turbine engine having a multistage axial compressor (not shown)
17 which pressurizes air 12 for discharge into an annular combustor (not shown).

18 **[0038]** The compressor discharge air is mixed with fuel in the combustor for generating hot
19 combustion gases 14 which flow through the turbine nozzle to high pressure turbine rotor
20 blades (not shown) which extract energy therefrom for powering the compressor. A low
21 pressure turbine (not shown) follows the high pressure turbine for extracting additional energy
22 from the combustion gases for driving an output shaft, which may be joined to an upstream
23 fan in an exemplary turbofan aircraft gas turbine engine application.

24 **[0039]** The exemplary turbine nozzle illustrated in Figures 1 and 2 includes a row of hollow
25 airfoils or vanes 16 fixedly joined at opposite ends thereof to corresponding radially outer and
26 inner bands 18,20. The bands are typically formed in arcuate segments including two vanes,
27 and the segments adjoin circumferentially to form complete rings having suitable
28 inter-segment seals therebetween. The individual vanes are typically brazed into
29 corresponding apertures in the outer and inner bands through which the pressurized cooling air
30 12 is delivered thereto.

1 [0040] Each of the nozzle vanes illustrated in Figures 2 and 3 includes a generally concave
2 pressure sidewall or side 22 and a circumferentially opposite, generally convex suction
3 sidewall or side 24. The two sides extend radially in span between the outer and inner bands,
4 and extend axially in chord between opposite leading and trailing edges 26,28.

5 [0041] As shown in Figure 3, the vanes are spaced circumferentially apart from each other,
6 and have airfoil configurations which define converging flow passages 30 between the
7 opposing pressure and suction sides thereof. The trailing edge 28 of one vane forms with the
8 suction side of the next adjacent vane forward of the trailing edge thereof a throat 32 of
9 minimum flow area between the vanes through which the combustion gases 14 are accelerated
10 during operation. The throat 32 is typically defined by a plane perpendicular to the suction
11 side of one vane to the trailing edge of the next vane.

12 [0042] In the exemplary embodiment illustrated in Figure 3, each vane 16 includes a
13 forward flow passage or cavity 34 and an aft flow passage or cavity 36 separated from each
14 other by an imperforate cold bridge 38. The forward cavity is located directly behind the
15 leading edge, and the aft cavity is separated therefrom by the cold bridge 38 which is
16 integrally formed between the two vane sides. The aft cavity is spaced forwardly from the
17 thin vane trailing edge 28 where space permits.

18 [0043] Corresponding forward and aft impingement baffles 40 are disposed in the two
19 cavities 34,36. The baffles are perforate and conventionally include small apertures through
20 which the pressurized cooling air 12 is firstly channeled in impingement against the internal
21 surfaces of the pressure and suction sides of the vane prior to discharge therefrom. The
22 cooling air is suitably received from the discharge end of the compressor and delivered
23 through inlet apertures in the outer and inner bands in the exemplary embodiment.

24 [0044] As shown in Figures 1 and 2, the aft cavity 36 is closed at its inner end in the inner
25 band and includes an inlet at its outer end in the outer band for receiving the cooling air. In
26 contrast, the forward cavity 34 is closed at its outer end in the outer band and includes an inlet
27 at its inner end in the inner band for receiving the cooling air. The internal bridge 38
28 illustrated in Figure 3 separates the forward and aft cavities from each other for separately
29 controlling cooling of the forward portion of the vane from cooling of the aft portion of the
30 vane separated along the bridge plane.

1 [0045] As initially shown in Figures 1 and 2, each vane includes identical patterns of outlet
2 holes extending through the sidewalls thereof, and distributed over the pressure and suction
3 sides for discharging the cooling air therefrom. The total flowrate of cooling air provided to
4 each nozzle vane is preferably predetermined and fixed at the desired design point for the
5 particular engine configuration. As indicated above, it is desired to limit the amount of the
6 pressurized cooling air bled from the compressor during operation for maximizing
7 efficiency of the engine.

8 [0046] The full pattern or complement of the outlet holes in each vane therefore collectively
9 effects a fixed, or reference flowrate of the cooling air being channeled firstly into the inside
10 of each vane and then discharged through the vane walls.

11 [0047] A pattern of outlet holes in the exemplary configuration illustrated in Figures 1-4
12 includes multiple radial rows of showerhead holes 42 bridging the leading edge 26 through
13 both pressure and suction sides. As best shown in Figure 5, the pattern also includes two rows
14 of axially inclined, film cooling gill holes 44 spaced aft from the showerhead holes along the
15 suction side 24.

16 [0048] As shown in Figures 2-4, the outlet hole pattern in this exemplary embodiment
17 further includes a row of conventional trailing edge slots 46 terminating at the trailing edge 28
18 along the pressure side 22, and having inlets extending upstream to and disposed in flow
19 communication with the aft cavity 36 for discharging air therefrom.

20 [0049] The pattern further includes one row of film cooling holes 48 extending through the
21 pressure side between the trailing edge slots and the aft cavity, and two rows of additional film
22 cooling holes 50 also extending through the pressure side, but adjacent to the aft end of the aft
23 cavity 36. Four additional rows of film cooling holes 52 are found in the pattern on the
24 pressure side of the vane adjacent the aft end of the forward cavity 34.

25 [0050] The various showerhead holes 42, gill holes 44, trailing edge slots 46, and film
26 cooling holes 48-52 have conventional configurations, and are typically inclined through the
27 corresponding pressure and suction sidewalls in common radial planes, without vertical
28 inclination along the vane span. In other embodiments, the holes may have compound
29 inclination angles both vertically along the vane span and horizontally along radial cross
30 sections of the vane.

1 [0051] As illustrated schematically in Figure 2, the turbine nozzle 10 may be otherwise
2 conventional and based on the first, pre-existing turbine nozzle disclosed above in the
3 Background section, but suitably modified. For example, the pre-existing, unmodified nozzle
4 vane is designated 54 in Figure 2 and is substantially identical to the modified or derivative
5 vane 16 illustrated therein, except for the modifications thereof as further described
6 hereinbelow.

7 [0052] For example, the pattern of eight-row outlet holes 42 and holes 46-52 is identical to
8 the pre-existing pattern in the first turbine nozzle described above enjoying successful decades
9 of commercial use. Even the two rows of gill holes 44 are found in the first pre-existing
10 turbine nozzle, but have modified configurations in the resulting derivative nozzle and vane.

11 [0053] More specifically, the multiple rows of showerhead holes 42, best illustrated in
12 Figure 4, include one row along the vane leading edge 26, four rows along the suction side 24,
13 and three rows along the pressure side 22 for a total of eight rows. These eight rows are
14 substantially identical to those found in the first parent nozzle disclosed above in the
15 Background section for providing distributed cooling of the vane in the immediate region of
16 the leading edge thereof.

17 [0054] However, as indicated above in the Background section, experience has uncovered
18 early signs of local distress of the vane immediately aft of the original showerhead holes on
19 the vane pressure side. Accordingly, a row of auxiliary showerhead holes 56 is added and is
20 spaced directly aft from the aft-most row of original showerhead holes 42 through the vane
21 pressure side 22. In other words, the auxiliary holes 56 introduce a ninth row of the
22 showerhead holes 42 bridging the vane leading edge, with four rows on the opposite sides
23 thereof, and one row along the leading edge itself.

24 [0055] In this way, the additional row of auxiliary holes 56 provides additional film cooling
25 in the immediate region thereof for reducing the local temperature distress discovered in this
26 region.

27 [0056] However, in view of the fixed or limited cooling air budget for the entire nozzle
28 vane, the additional row of auxiliary holes 56 cannot be added without a corresponding
29 modification of the vane to offset or counterbalance the additional airflow therethrough, and
30 without compromising cooling effectiveness of the various outlet holes of each nozzle vane,

1 and without compromising performance of the nozzle vanes themselves, and without
2 compromising cooling performance of the combustor liners which share the use of the
3 compressor discharge air for cooling thereof.

4 **[0057]** Figure 4 illustrates schematically the original configuration and location of the
5 original gill holes, designated 58, on the suction side of the nozzle vane previously found in
6 the parent, first turbine nozzle disclosed above in the Background section. The original gill
7 holes 58 were closely spaced together, and inclined axially through the suction sidewall. The
8 original gill holes were cylindrical in configuration with a nominal diameter of about 0.86
9 mm.

10 **[0058]** The two rows of modified gill holes 44 match the general pattern of the original two
11 rows of gill holes 58 but are modified in configuration, size, and relative placement to offset
12 or counterbalance the added discharge of the cooling air through the auxiliary holes 56 for
13 maintaining substantially the same collective or reference flowrate of the cooling air through
14 each nozzle vane. In other words, the total flowrate of cooling air used in each nozzle vane
15 remains substantially the same with or without the use of the auxiliary holes 56, in
16 combination with the specific configuration of the gill holes.

17 **[0059]** For example, the showerhead holes 42 and auxiliary holes 56 preferably have
18 substantially equal size as represented by the nominal diameters thereof, or their flow areas,
19 with the modified gill holes 44 being larger in size than the showerhead and auxiliary holes,
20 but smaller in size than their original gill counterparts 58.

21 **[0060]** Both the showerhead holes 42 and auxiliary holes 56 illustrated in Figure 4 have
22 cylindrical configurations extending transversely through the vane sidewalls, with cylindrical
23 inlets on the inside of the vane and cylindrical outlets on the outside of the vane, which vary
24 slightly in configuration to conform with the convex curvature of the vane around the leading
25 edge.

26 **[0061]** Correspondingly, the gill holes 44 have conventional diffusion configurations with
27 cylindrical inlets on the inside of the vane, and diverging, generally trapezoidal outlets on the
28 outside of the vane. The diffusion gill holes 44 replace the conventional cylindrical
29 configuration of the original gill holes 58.

30 **[0062]** As shown in Figures 4 and 5, the modified gill holes 44 include a forward row

1 adjacent the showerhead holes 42, in substantially the same axial location as in the first
2 pre-existing turbine nozzle described above, disposed in flow communication with the
3 forward cavity 34 for receiving therefrom the spent impingement air for discharge from the
4 vane. The gill holes 44 also include an aft row thereof spaced aft from the forward row
5 adjacent the junction of the suction side 24 and the cold bridge 38, and also disposed in flow
6 communication with the forward cavity 34 for receiving the spent impingement air therefrom.

7 **[0063]** The added row of auxiliary holes 56 in the vane pressure side is compensated by the
8 preferred modification of the two rows of gill holes 44. The difference in pressure and
9 temperature distribution of the combustion gases on the opposite sides of the nozzle vane
10 permit modification of the gill holes to compensate for the added auxiliary holes without
11 compromising cooling and aerodynamic performance of the turbine nozzle, while improving
12 the two different local stress regions at the pressure side leading edge and suction side trailing
13 edge, all without increasing the required flowrate of the cooling air for the nozzle vane.

14 **[0064]** The smaller flow area diffusion gill holes 54 effectively offset the increased flow
15 area of the auxiliary holes 56 notwithstanding the differential pressure acting thereacross due
16 to the different pressure distributions on the pressure and suction sides of the vane. The
17 diffusion form of the gill holes 44 is more effective for cooling the vane suction side than their
18 parent cylindrical counterparts, which is a conventionally known benefit.

19 **[0065]** Furthermore, the axial spacing between the two rows of gill holes 44 may be
20 increased as shown in Figure 4 over the previous close spacing used for the original
21 cylindrical gill holes 58. By relocating the aft row of diffusion gill holes to the junction with
22 the cold bridge 38, the cooling air film discharged therefrom more effectively carries to the
23 trailing edge of the vane for reducing the local temperature distress at the suction side trailing
24 edge.

25 **[0066]** As shown in Figure 3, by moving the aft row of gill holes 44 to the junction with the
26 cold bridge 38, the aft row is disposed generally midway between the outlet throat 32 of the
27 flow passage 30 and the adjacent vane leading edges defining the inlet to that flow passage.

28 **[0067]** It is noted from the second pre-existing turbine nozzle disclosed above in the
29 Background section that the introduction of diffusion gill holes for cylindrical counterparts,
30 and the increased spacing therebetween, is conventionally known to reduce the local

1 temperature distress at the trailing edge suction side. But, that solution is for a differently
2 configured turbine nozzle with a different pattern of outlet holes, and that solution maintains
3 the same nominal flow area size of the diffusion holes as for their parent cylindrical
4 counterparts.

5 **[0068]** In the present configuration of the turbine nozzle, the auxiliary showerhead holes 56
6 may be added for reducing the local temperature distress at the leading edge pressure side,
7 with the additional airflow therethrough being compensated for or counterbalanced by the
8 decrease in airflow through the modified diffusion gill holes.

9 **[0069]** Accordingly, the derivative turbine nozzle and modified vanes thereof may remain
10 substantially identical to their pre-existing, parent turbine nozzle and unmodified vanes which
11 have enjoyed decades of successful commercial use, with the specific modifications thereof
12 being limited to the introduction of the auxiliary holes 56 and corresponding modification of
13 the gill holes 44. The derivative turbine nozzle may therefore be used in retrofitting the
14 existing commercial fleet of turbofan gas turbine engines which use the unmodified parent
15 turbine nozzles. The derivative turbine nozzle can reduce the local temperature distress at the
16 pressure side leading edge and suction side trailing edge for further increasing the durability
17 and life of the turbine nozzle, and increasing the intervals between maintenance outages
18 therefor.

19 **[0070]** The derivative turbine nozzle illustrated in Figure 2 includes the original pattern of
20 eight rows of showerhead holes 42, with each row consisting of sixteen (16) holes between the
21 outer and inner bands, with each hole 42 having a diameter of about 0.66 mm.
22 Correspondingly, the added auxiliary holes 56 preferably consist of sixteen (16) holes in the
23 row distributed between the outer and inner bands, with each of the auxiliary holes having a
24 diameter of about 0.66 mm. In this way, the auxiliary holes 56 join the other showerhead
25 holes 42 in a complete pattern of identical holes which effectively cool the leading edge region
26 of each vane subject to impingement of the hottest combustion gases during operation.

27 **[0071]** The modified gill holes 44 preferably consist of twenty-five (25) holes per row
28 between the outer and inner bands, with each gill hole 44 having an inlet diameter of about
29 0.76 mm, with an outlet diverging therefrom in a conventional manner. The number of
30 modified gill holes 44 identically matches the number of cylindrical gill holes 58 found in the

1 parent first turbine nozzle disclosed above.

2 **[0072]** Accordingly, by the precise introduction of the row of auxiliary holes 56 and the
3 corresponding modification of the gill holes 44 in the otherwise conventional turbine nozzle, a
4 significant improvement in durability and life of the nozzle may be obtained without adversely
5 affecting either aerodynamic or cooling performance of the nozzle. The gill holes are reduced
6 in size to offset the added flow area of the auxiliary holes without compromising cooling
7 performance of the gill holes themselves.

8 **[0073]** The gill holes are modified from cylindrical configurations to conventional diffusion
9 configurations to increase their effectiveness, notwithstanding the loss in airflow therethrough.

10 And, the rows of gill holes are further spaced apart from each other for effecting cooling air
11 films which extend downstream therefrom to the trailing edge of the vane for effectively film
12 cooling the vane suction side, including the discovered local temperature distress region at the
13 trailing edge thereof.

14 **[0074]** Furthermore, computer analysis of the performance of the so-modified turbine nozzle
15 predicts that the entire outlet hole pattern combined with the modification of the gill holes
16 provides effective and balanced cooling of the entirety of the nozzle vane, while balancing the
17 split in cooling airflow between the pressure and suction sides thereof.

18 **[0075]** While there have been described herein what are considered to be preferred and
19 exemplary embodiments of the present invention, other modifications of the invention shall be
20 apparent to those skilled in the art from the teachings herein, and it is, therefore, desired to be
21 secured in the appended claims all such modifications as fall within the true spirit and scope of
22 the invention.

23 **[0076]** Accordingly, what is desired to be secured by Letters Patent of the United States is
24 the invention as defined and differentiated in the following claims in which we claim:
